Pathophysiology of Infective Endocarditis (IE) Associated with Intravenous Drug Use

Kaleigh Cline BSN, RN
Otterbein University, Westerville, Ohio

Introduction

• Intravenous drug use (IVDU) poses many risks to those who use them. One of the risks being infectious endocarditis.
• Infective endocarditis (IE) is an infectious microbial disease of the heart subvalvular endothelium.
• The characteristic lesion consists of the presence of vegetation that can settle in the subvalvular valves, tendon cords or mural endocardium” [2018, p. 1].
• Complications of IE include: congestive heart failure, embolization of septic emboli to other organs, perianuremic extension of infection, metastatic infection of infection, mycotic aneurysms, and aneurysmal dilatation (Baddour, et al., 2015, pp. 32-37).
• Contemporary multicentre assessments of outcomes in IE have estimated “Infective endocarditis (IE) is an infectious microbial disease of the heart subvalvular endothelium.” [Baddour, et al., 2015, p. 1].

Signs & Symptoms

Most Common
• High fever (usually above 100.4°F)
• Chills
• Night sweats
• Headache
• Shortness of breath
• Graft
• Cardiac murmurs
• Fatigue
• Muscle and joint pain

Other Symptoms

• Proteinuria
• Splinter hemorrhages

Patho-Pathogen Interaction: Pathogens adhere to the everted esophageal matrix proteins, referred to as Microbial Surface Component Reacting with Adhesive Matrix Molecules, released by the non-bacterial thrombotic vegetation. After the pathogen adheres to the vegetation, colonization and invasion of the myocardium occurs and maintains the inflammatory and coagulation processes.

Underlying Pathophysiology

Underlying Lesion: Degenerative processes such as fibrosis, calcification, congenital heart disease, mechanical lesions secondary to material implantation, and turbulent blood flows (IVDU) causes endocardial damage. This then exposes the extracellular matrix and results in apoptosis of endothelial cells which then produces tissue factor and a non-bacterial thrombosis formation. This thrombotic formation is known as a “vegetation.” (Thuny, 2016, p. 1). The vegetation will continue to grow (neoangiogenesis) and destroy the valve tissue (Thuny, 2016, p. 1-2).

In the instance of IVDU, the pathogen is introduced into the host via bacteria located on the skin, the needle, or the substance being injected. The key factor required for IVDU to cause IE is myocardial tissue damage that has produced a vegetation. Research shows that chronic IVDU can cause non-bacterial vegetation on heart valves due to the repetitive damage from injected particular matter (UpToDate, 2018).

According to Lapkus and Pradlow (2015), “the risk of IE in IVDU is estimated at 2%-5% per year” (p. 631).

“Staphylococcus aureus accounts for more than half of cases of IE among IVDUs. Streptococcus and enterococcus are the next most common pathogens. Less common, and gram-negative bacilli can also cause IE in IVDUs” (UpToDate, 2018).

Upper panel: Infective endocarditis producing organism, increased production of adhesion factors, leading to increased aggregation and proinflammatory cytokine production with propagation of vegetation.

Lower panel: Organism possessing decreased adhesion capacity, leading to lower risk of inflammation and no endocarditis.

Significance of Pathophysiology

IE is a significant diagnosis because of its ability to affect almost every vital body system.

Heart Failure - Heart failure is the most common complication from IE and can often lead to surgical intervention (Habib, et al., 2015, p. 26). Myocardial tissue death from a bacterial vegetation causes valvular insufficiency and regurgitation, leading to heart failure.

Bacterial Infection - IE can lead to a persisting infection (positive blood cultures for greater than 7-10 days) and a persistent extension of the original infection. Some pathogens in IE can be resistant to antibiotics and be even more difficult to treat. According to Habib, et al., (2015), “Persisted extension of IE is the most frequent cause of uncontrolled infection and is associated with a poor prognosis and high likelihood of the need for surgery” (p. 26).

Embolism - Embolic events are very frequent (up to 25%) have already occurred upon diagnosis of IE and can be fatal. Splenic and brain emboli are the most common site with left-sided IE. Pulmonary embolism and puerile lead embolism are the most common type with right-sided IE. The risk of embolism falls from 20%-50% to 6-12% after IV antibiotic initiation (Habib et al., 2015, p.20). Therefore, early diagnosis and initiation of IV antibiotics in IE is imperative.

Endocarditis produces- When a piece of the vegetation embolizes and lodges in the spleen and infect the organ is often asymptomatic. Although not as common, splenic abscesses also may occur and require surgical treatment.

Cardiac Disturbances - Myocarditis and pericarditis may occur from abscess formation from IE. This may lead to ventricular arrhythmias that often prove fatal. Pericardial effusions and aneurysms involving the pericardium may also occur. Conduction abnormalities such as heart blocks and atrial fibrillation may occur due to the spread of infection beyond the endocardium, through the valves and into conduction pathways. Myocardial ischemia or myocardial infection may also occur if an embolus travels to the coronary arteries.

Renal Failure - Acute renal dysfunction (AED) occurs in about 6-30% of IE patients and may worsen the prognosis of IE as AED is independently associated with increased hospital mortality (Habib et al., 2015, p. 30). This complication of IE may change the dosage of IV antibiotics to allow for renal considerations.

Embolic events are very frequent (up to 25%) have already occurred upon diagnosis of IE and can be fatal. Splenic and brain emboli are the most common site with left-sided IE. Pulmonary embolism and puerile lead embolism are the most common type with right-sided IE. The risk of embolism falls from 20%-50% to 6-12% after IV antibiotic initiation (Habib et al., 2015, p. 20). Therefore, early diagnosis and initiation of IV antibiotics in IE is imperative.

Underlying Pathophysiology

Implications for Nursing Care

• Assess patients for signs and symptoms of IE and report findings timely to the physician.
• Obtain a thorough health history, specifically regarding cardiac and IVDU history.
• If a patient has a confirmed IE (especially left sided), monitor the patient for complications such as embolization of the vegetation to other organs (decreased urine output, confusion, abdominal/hack pain, shortness of breath, increasing chest pain).
• Nurses must also know the correct procedures for drawing blood cultures in order to avoid contamination of the specimen.
• The nurse must also be able to properly educate the patient on IVDU cessation and the instance of reoccurrence of IE in IVDU.

References

• Infective endocarditis is a serious condition associated that if not treated, can lead to death.
• IVDU has an affect on many other vital body systems.
• IVDU puts the patient at risk for developing IE.
• Key pathophysiology points:
  - Damage to the myocardial tissue makes tissue prone to bacterial attachment.
  - IVDU allows an easy route for bacteria to enter the bloodstream and attach to the valve (vegetation).
  - Vegetation growth damages the valve to dysfunction and can lead to other organ damage (as earlier discussed.)
• Educating patients with IE closely for complications.
• Nurses must monitor patients with IE closely for complications.
