Introduction

Hyperglycemic hyperosmolar state (HHS) is an acute complication associated with diabetes mellitus. HHS has been known by several other names in the past. These labels include Hyperosmolar Nonketotic Coma, Hyperosmolar Hyperglycemic Nonketotic Coma, and Hyperglycemic Hyperosmolar Nonketotic Syndrome (Hackel, 2014). HHS is characterized by severe hyperglycemia, profound dehydration, and is often accompanied by altered mental status. Less than 1% of diabetes-related admissions are due to HHS, but mortality rates are estimated to be 10% to 20% (Lenahan & Holloway, 2015). HHS typically affects the older adult population, with the average age of HHS patients being 60 years (Collopy, Kivlehan, & Snyder, 2013). The patient with HHS commonly has type 2 diabetes (Pasquel, Hackel, & Umpierrez, 2014). Up to 40% of those affected have never been diagnosed with diabetes prior to developing HHS (Collopy et al., 2013).

HHS is a medical emergency. The incidence of HHS is expected to rise in the future due to the increase in the occurrence of type-2 diabetes (Lenahan & Holloway, 2015). It is important for healthcare providers to recognize HHS in order to provide appropriate care for the patient and reduce the mortality rates associated with this acute complication.

Patient Presentation

The patient with HHS presents with altered mental status, blood glucose level of >600 mg/dL, and with or without ketones present in the urine (Van Ness-Ottmann & Hack, 2013). Poor skin turgor and elevated serum osmolality are present due to the profound dehydration caused by severely elevated blood glucose levels (Van Ness-Ottmann & Hack, 2013). The patient may exhibit polyuria and polyphagia, but these compensatory mechanisms may possibly be blunted by the severe dehydration and altered mental status that are characteristic of HHS (Hackel, 2014). Because of the endogenous insulin present in type 2 diabetics, adipose tissue is not broken down for energy, and therefore metabolic acidosis does not occur (Pollick & Funk, 2013).

Signs & Symptoms

- Blood glucose level >600 mg/dL
- Polyuria
- Polyphagia
- Poor skin turgor
- Dryness
- Confusion
- Coma

In type 2 diabetes mellitus, the body tissues become increasingly resistant to the effects of insulin, which leads to a relative insulin deficiency (Van Ness-Ottmann & Hack, 2013). There is usually a precipitating event, such as an infection (i.e., pneumonia, urinary tract infection) or medication side effect, that initiates hyperglycemia in the patient (Hackel, 2014). The body responds to the stress by releasing hormones such as catecholamines, cortisol, glucagon, and growth hormone that cause increased glucose levels (Pasquel & Umpierrez, 2014). Insulin resistance causes inadequate use of the glucose by the peripheral tissues, which also contributes to the rising hyperglycemia (Pasquel & Umpierrez, 2014).

Increased blood glucose levels cause an increase in the osmolality of extracellular fluid, which leads to a shift in fluid from the cells to the extracellular space (Pasquel & Umpierrez, 2014). As the glucose level rises, the kidneys attempt to filter the glucose from the blood to the urine via osmotic diuresis (Hackel, 2014). The cells become dehydrated, the blood becomes concentrated, and the lack of fluid restricts the ability of the kidneys to rid the body of excess glucose (Hackel, 2014). Thirst is triggered in an attempt to counteract the dehydration (Hackel, 2014).

The alterations in electrolytes due to the dehydration lead to the mental status changes (ranging from stupor to coma) associated with HHS (Pasquel & Umpierrez, 2014).

Pathophysiological Process

The endogenous insulin present in patients with HHS allows the process to progress over the course of days to weeks (Hackel, 2014). This insulin onset enables the body to adapt to the hyperglycemic state (Hackel, 2014). Because of this adaptation, the patient may not seek medical care until they are critically ill (Hackel, 2014). This failure to seek care is compounded by the mental status changes that accompany HHS (Hackel, 2014).

During the acute phase of HHS, neurological surrogates and completion measures must be attempted and reduced. Seizures should be avoided due to the critical state of HHS patients once they present for care. HHS must be carefully monitored and managed in order to prevent complications. The expected increase in incidence of HHS and the high mortality rate associated with it makes understanding the unique aspects of this disease process important to health care providers and their patients.

Significance of Pathophysiology

The endogenous insulin present in patients with HHS allows the process to progress over the course of days to weeks (Hackel, 2014). This insulin onset enables the body to adapt to the hyperglycemic state (Hackel, 2014). Because of this adaptation, the patient may not seek medical care until they are critically ill (Hackel, 2014). This failure to seek care is compounded by the mental status changes that accompany HHS (Hackel, 2014).

Implications for Nursing Care
